A load management system provides an interface between a power input and several switched power outputs and un-switched power outputs. A controller groups the switched power outputs into one or more load groups based on a switched current limit determined for the system and the measured currents of the electrical loads. The load groups are defined so that the sum of electrical load currents in each load group does not exceed the switched current limit. The controller also activates one or more switches to apply electrical power to the load groups according to a power sequence. A method for distributing electrical power to electrical loads using load groups is also provided.

ELECTRICAL LOAD MANAGEMENT SYSTEM AND METHOD

CROSS-REFERENCES

This application is a continuation application of U.S. application Ser. No. 13/174,637, filed Jun. 30, 2011, which claims the benefit of U.S. Provisional Application No. 61/360,277, filed Jun. 30, 2010, and U.S. Provisional Application No. 61/383,224, filed Sep. 15, 2010, the contents of each being incorporated by reference in their entirety, and the benefit of priority of each is claimed herein.

FIELD

Embodiments of the invention generally relate the management of electrical loads and more particularly relate to load management of electrical devices requesting more power than is available from a common power source.

BACKGROUND

There are many instances in which multiple electrical loads are connected to and powered by a single, common electrical power source. The common power source may be designed to provide sufficient power for all of the electrical loads, to ensure that each load is adequately powered.

In certain circumstances, though, it may be desirable to provide power to a number of electrical loads from a power source that does not supply enough power to adequately power all of the electrical loads. Requesting more than the available power may in some cases lead to inadequate device performance as well as, or in addition to, activation of protection circuitry built into the power source. For example, an overload can result due to a circuit breaker tripping, an over-current or current limiting circuit causing a power source voltage fold-back, or other method of limiting the distributed power to a known acceptable level without exceeding the source power available. Activation of the protection features can lead to reduced or no power reaching the electrical load(s) that needs powering. Consequently, the functionality of the load(s) attached to the power source can be reduced or disabled.

Source power might be limited for a number of reasons, including, for example, the size of wiring, circuit breaker limits, National and International Electrical Codes, development of harmonic currents, vehicle electrical power limits, or limits stemming from currently available alternative energy sources such as solar or wind-generated power.

One example of an arrangement that may be subject to these types of limitations is a computer notebook or laptop charging cart or charging station. There are many situations in which multiple laptop computers are simultaneously used. For example, multiple laptop computers are widely used in classrooms for educational purposes. In many cases, 10-40 notebooks are simultaneously used in the classroom. Typical laptop carts are cabinets with shelves for the laptops to rest on and power and/or communication connections for charging and/or using the laptops.

In many cases the power consumption required to simultaneously charge and/or use many notebooks can exceed the limits set forth by the National Electrical Code and foreign equivalents for alternating current (AC) line voltages. This type of power consumption may also often exceed the capacity of a direct current (DC) power source that provides the bulk charge current for the electronics that charge notebook batteries directly. Known charging methods require a user to

2

manually switch power between groups of notebooks or batteries to keep the peak current draw within the limitations of the physical configuration. If computer carts or charging stations are provided with auxiliary power take-offs, known methods also require the user to manually switch on any external devices to be powered while internal devices are switched off.

SUMMARY

According to an aspect of the invention an electrical load management system is provided for switching electrical power among a number of electrical loads. The load management system include an electrical power input that couples the load management system with a common power source and a plurality of electrical power outputs that couple with multiple electrical loads. A number of switches couple the power input to the power outputs. A current sensor is coupled to the power outputs and senses a current drawn by one or more of the power outputs. A controller is coupled to the switches and the current sensor, and is configured to measure a current drawn by each of the power outputs and respective electrical loads. The controller also groups the power outputs and electrical loads into one or more load groups based on a switched current limit determined for the system and the measured currents of the electrical loads. The load groups are defined so that the sum of electrical load currents in each load group does not exceed the switched current limit. The controller is also configured to activate the switches to apply electrical power from the common power source to the load groups according to a power sequence.

Another aspect of the invention provides a method for distributing electrical power to electrical loads. The method includes measuring a current drawn by each of a number of electrical loads coupled to a common power source through a load management system. The electrical loads are grouped into one or more load groups based on a switched current limit and the measured currents of the electrical loads. The grouping is configured so that, for each load group, a sum of the measured currents of the electrical loads in the load group does not exceed the switched current limit. The method also includes applying electrical power from the common power source to the load groups by switching the electrical power to each of the load groups according to a power sequence.

Another aspect of the invention provides for managing the electrical load of a charging station. The charging station includes an electrical power input configured to couple the charging station with a common power source and multiple switched electrical power outputs configured to couple the charging station with a number of electrical loads for charging. The charging station also includes a number of switches coupled between the power input and the switched power outputs for applying electrical power from the common power source to the switched power outputs. A current sensor is coupled to the switched power outputs for sensing a current drawn by one or more of the switched power outputs. In one embodiment, an optional un-switched power output is coupled to the electrical power input and configured to couple the charging station with an un-switched electrical load, while a second current sensor coupled to the un-switched output senses a current drawn by the un-switched power output. In both embodiments, the charging system includes a controller coupled to the switches, the first current sensor, and optionally the second current sensor. The controller measures with the first current sensor a current drawn by each of the electrical loads respectively coupled to the switched power outputs. After measuring the currents, the controller groups

3

the switched power outputs and respective electrical loads into one or more load groups based on a switched current limit and the measured currents of the electrical loads such that, for each load group, a sum of the measured currents of the electrical loads in the load group does not exceed the switched current limit. The controller is also configured to activate the switches to apply electrical power from the common power source to the load groups according to a power sequence. In some cases the controller is configured to determine a switched current limit based on the current drawn by the optional un-switched power output and/or a current limit of the common power source.

These and various other features and advantages will be apparent from a reading of the following detailed description.

BRIEF DESCRIPTION OF THE DRAWINGS

The following drawings are illustrative of particular embodiments of the present invention and therefore do not limit the scope of the invention. The drawings are not to scale (unless so stated) and are intended for use in conjunction with the explanations in the following detailed description. Embodiments of the present invention will hereinafter be described in conjunction with the appended drawings, wherein like numerals denote like elements.

FIG. 1 is a high-level diagram illustrating multiple functions of a load management system in accordance with an embodiment of the invention.

FIG. 2 is a high-level schematic of a load management system in accordance with an embodiment of the invention.

FIG. 3 is a flow diagram illustrating a method for applying power to a number of un-switched and switched electrical devices in accordance with an embodiment of the invention.

FIG. 4 is an illustration of an indicator panel for a load management system in accordance with an embodiment of the invention.

FIG. 5A is a perspective view of a charging station in accordance with an embodiment of the invention.

FIG. 5B is a perspective view of a charging station in accordance with an embodiment of the invention.

FIG. 5C is another perspective view of the charging station of FIG. 5B.

FIG. 5D is a rear perspective view of the charging station of FIG. 5B.

FIG. 6A is a top plan view of a cart in accordance with an embodiment of the invention.

FIG. 6B is a front perspective view of the cart of FIG. 6A.

FIG. 6C is a front plan view of the cart of FIG. 6A.

FIG. 6D is a side plan view of the cart of FIG. 6A.

FIG. 7A is a front perspective view of a cart with its doors opened in accordance with an embodiment of the invention.

FIG. 7B is a rear perspective view of the cart of FIG. 7A with its rear panel removed.

FIG. 7C is a front perspective view of an auxiliary power outlet having a cover in the open position in accordance with an embodiment of the invention.

FIG. 7D is a front perspective view of an auxiliary power outlet having a cover in the open position in accordance with an embodiment of the invention.

FIG. 8 is a high-level schematic of a power supply system for a notebook charging cart in accordance with an embodiment of the invention.

FIGS. 9A-9C are a flow diagram illustrating a method of charging multiple notebook computers in accordance with an embodiment of the invention.

4

FIGS. 10A-10B are a flow diagram illustrating a method of charging multiple notebook computers in accordance with an embodiment of the invention.

FIGS. 11A-11C are a flow diagram illustrating a method of charging multiple notebook computers in accordance with an embodiment of the invention.

FIGS. 12A-12B are a flow diagram illustrating a method of charging multiple notebook computers in accordance with an embodiment of the invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The following detailed description is exemplary in nature and is not intended to limit the scope, applicability, or configuration of the invention in any way. Rather, the following description provides some practical illustrations for implementing exemplary embodiments of the present invention. Examples of constructions, materials, dimensions, and manufacturing processes are provided for selected elements, and all other elements employ that which is known to those of ordinary skill in the field of the invention. Those skilled in the art will recognize that many of the noted examples have a variety of suitable alternatives.

FIG. 1 is a high-level diagram illustrating a load management system **100** according to an embodiment of the invention. In general, the system **100** provides an interface between a power source **102** and multiple electrical loads **104**, controlling distribution of electrical power from the power source **102** to one or more of the electrical loads **104**. The load management system **100** can provide a useful solution for managing electrical loads in a variety of contexts. For example, the system **100** can be used for powering and/or charging large numbers of laptop computers (also referred to herein as “notebook computers” or “notebooks”) used in a school classroom or in a business setting. The system **100** could also be used to manage electrical power for a group of mobile computing devices, including for example, a tablet computer, a cell phone, a smart phone, a personal digital assistant, a camera, a music player, and/or a global positioning satellite (GPS) device. In some instances the system **100** may be useful for providing electrical power to a number of electrical loads coupled to a vehicle (e.g., automobile, aircraft, etc.) power system. Of course, these are just a few contemplated examples for using the system **100**, and the system **100** may also be useful in other situations.

In some cases the load management system **100** could be useful for managing delivery of electrical power from an alternative energy source such as wind or solar power to multiple electrical loads. Other energy sources may be coupled to the system **100**, and the particular format or configuration of the electrical power may vary depending upon the requirements of a particular embodiment. As will be discussed further herein, in some cases the power source **102** may provide AC power or DC power. In some embodiments the electrical power is pulsed, sinusoidal, non-sinusoidal, or has another waveform.

As shown in FIG. 1, the load management system **100** provides a number of functions that may be useful for distributing power to the multiple electrical loads **104**. In particular, the system **100** provides power source protection **110**, inrush current limiting **112**, control logic **114**, current sensing **116**, switched power distribution **118**, and non-switched power distribution **120**. According to some embodiments, the functionality of the load management system **100** can be implemented and provided by hardware and firmware or software, or a combination of hardware, firmware, and software. The

5

illustrated system **100** is just one example of a load management system described herein, and other embodiments may provide all or only some of the functions shown in FIG. 1, or may provide different functions not depicted. Several of the functions for the illustrated load management system **100** will be described in more detail hereinafter.

FIG. 2 is a high-level schematic of a load management system **200** in accordance with an embodiment of the invention. The system **200** generally provides an interface between an electrical power input **202** and multiple electrical power outputs **204**. The power outputs **204** are coupled to the input through switches **206**, which serve to selectively transmit electrical power to the power outputs **204**. Control of the switches **206** and thus distribution of power from the power input **202** to one or more of the power outputs **204** is controlled and managed by a controller **208**. A current sensor **210** is coupled to the electrical power outputs **204** and the controller **208**, thus allowing the controller **208** to make decisions about power distribution based on measured currents drawn by one or more of the power outputs **204**. In this embodiment the load management system **200** also includes two un-switched power outputs, including an un-switched auxiliary power output **212** and an un-switched networking power output **214**. The networking power output **214** is coupled to the first current sensor **210**, which also provides measurements of current drawn by the networking power output **214**. A second current sensor **216** is coupled to the un-switched auxiliary output **212** and provides measurements of current drawn by the auxiliary output **212**.

Referring again to FIG. 2, the electrical power input **202** is configured to couple the load management system with a single, common power source (not shown). In this embodiment, the power input **202** is a power outlet and site power is brought into the system **200** through a power cord and connected plug. Other types of electrical power inputs may also be used, including other removable connectors, as well as hard-wired connections. In some embodiments, the electrical power is then distributed to the system **200** through a protection and conditioning circuit **220**. The protection and conditioning circuit **220** includes circuit breakers and/or resettable fuses (e.g., PTC devices) and a line filter to control emissions from the rest of the load management system **200** and electrical loads attached to the power outputs **204**. The load management system **200** is configured in this example to receive AC power at the power input **202**. Other embodiments may be configured to receive DC power.

The load management system **200** receives the electrical power through the power input **202**, and then routes it to one or more of the power outputs **204** through switches **206**. The power outputs **204** are configured to couple the load management system with one or more electrical loads (not shown in FIG. 2). In the example shown in FIG. 2, the power outputs **204** are configured as power outlets that can receive a plug connected to an electrical load. Other types of connections may be used depending upon the situation, including outputs hard-wired to the electrical loads.

The switches **206** are coupled between the power input **202** and the power outputs **204**. Accordingly, the power outputs **204** are also referenced as “switched” power outputs. The switches **206** can be implemented using any suitable switching device known in the art. Examples include, but are not limited to, solid-state relays (AC and DC), triacs (AC), and MOSFETS (DC). The switches **206** are coupled to the controller **208**, which operates the switches through, e.g., low-level control logic signals.

The controller **208** receives operating power from the power input **202** via an input **222**. In the case that the electrical

6

power is AC, the controller **208** may also include an AC/DC converter for generating a DC signal to power the controller **208**. The controller **208** includes a processing component **224** configured to provide the desired control for the system **200**. The processing component can be implemented in any suitable combination of hardware, firmware, and/or software. In some cases the processing component includes a microcontroller and associated firmware stored in integrated memory. In one example the processing component **224** is implemented with a programmable integrated circuit (PIC) or a programmable logic device (PLD), though other types of programmable processors are also contemplated.

As shown in FIG. 2, the controller **208** is coupled to the current sensor **210**, which is in turn coupled to each of the power outputs **204** through the switches **206**. The current sensor **210** can be implemented using any suitable approach, including, for example, a resistive shunt, a Hall-effect sensor, or an inductive sensor, among others. Through the sensor **210**, the controller **208** can monitor and measure the current drawn by one or more power outputs **204** (e.g., by the electrical load coupled to the output) alone or in various combinations. To measure a current drawn by a particular power output **204**, the controller **208** is configured to activate the switch **206** corresponding to the particular power output **204** while deactivating the switches for the other power outputs. The controller **208** then uses the current sensor **210** to monitor the current drawn from the power input **202**.

In the example shown in FIG. 2, a single current sensor **210** is used to measure current drawn by each of the electrical power outlets **204**. It is also contemplated that multiple current sensors could be used to more quickly (e.g., simultaneously) measure currents drawn by multiple electrical power outputs. For example, a current sensor could be positioned along each of the circuit branches leading to a particular power output **204**.

According to some embodiments, the controller **208** is configured to distribute the available electrical power from the power input **202** to the power outputs **204** by grouping the power outputs **204** (and respective loads) and then selectively applying the electrical power to the groups of power outputs according to a power sequence. It has been determined that this can be a useful methodology for powering electrical loads connected to the power outputs **204**, especially in cases in which the combined current drawn by the power outputs **204** and respective electrical loads (not shown) may be greater than the current provided by the electrical power input **202**. According to this approach, the controller **208** is configured to measure the current drawn by each of the switched power outputs **204** and then group the power outputs **204** and respective electrical loads into one or more load groups based on the measured currents and a determined switched current limit. In one embodiment the switched power outputs **204** are grouped such that a sum of the measured currents of the power outputs **204** in a particular group does not exceed the switched current limit. The controller **208** can then activate the appropriate switches **206** in order to apply the electrical power to the defined groups in sequence.

The switched current limit is a determined threshold that represents a desired limit for the amount of electrical power being applied to the power outputs **204** from the power input **202** at any one time. The switched current limit can be determined using a number of factors, including, for example, the current capacity of the electrical power input **202**. As discussed below, in some circumstances the switched current limit can also or alternatively be determined based on an amount of electrical power distributed to outputs other than the switched outputs **204**.

According to some embodiments, a load management system can also provide un-switched (e.g., continuous) electrical power to one or more power outputs. As shown in FIG. 2, the load management system **200** includes two un-switched power outputs, namely an un-switched auxiliary power output **212** and an un-switched networking power output **214**. The networking power output **214** is coupled to the first current sensor **210**, which can provide a measurement of the current drawn by the networking power output **214**. A second current sensor **216** is coupled to the un-switched auxiliary output **212** and provides measurements of current drawn by the auxiliary output **212**.

Any desirable number of un-switched power outputs can be included in the load management system **200**. A current sensor coupled to an un-switched output can be useful to measure the current drawn by the un-switched output. For example, the current sensor **216** in the load management system **200** allows the controller **208** to readily determine the auxiliary port current, which may vary or periodically shut off depending upon the type of load connected to the port **212**. In addition, the first current sensor **210** allows the controller **208** to easily determine the current drawn by the networking power output **214** when the switches **206** have been deactivated.

Powering electrical loads through the un-switched power outputs allows the load management system **200** to prioritize electrical power distribution for those loads over the loads connected to the switched power outputs **204**. For example, the un-switched power outputs **212**, **214** are not subject to the switched power sequence used with the switched outputs **204**, and thus the un-switched outputs and connected electrical loads can receive continuous power while the switched outputs **204** may only receive intermittent power in some cases. In addition, in some cases a portion of the available electrical power from the electrical power input **202** is effectively dedicated to the un-switched power outputs, thus decreasing the amount of electrical power available for distribution to the switched power outputs **204**. Accordingly, in some cases the switched current limit for the switched outputs **204** is determined based upon the current(s) drawn by the un-switched load(s).

As an example, in one embodiment the controller **208** is configured to sense through the current sensor **216** if an external un-switched load connected to the auxiliary port **212** is powered on. The controller **208** measures the current drawn by the auxiliary port **212** and then subtracts this measured current from the current previously available to the switched power outputs **204**. The switched current limit for the switched power outputs can thus be determined or adjusted based on the amount of electrical power being reserved for the un-switched power outputs and loads. In some cases this approach can maximize the current available to the un-switched outputs **212**, **214**, while still providing a reduced power level to the switched power outputs **204**. Once the un-switched load or device is turned off or unplugged from the un-switched output, controller **208** can automatically increase the switched current limit for the switched outputs.

A load management system, such as the system **200** illustrated in FIG. 2, can be modified to be compatible with a wide variety of applications, and may be incorporated into a number of larger systems. As will be discussed with reference to FIGS. 5-12, some embodiments of the invention provide a load management system configured for charging a number of laptop computer batteries, while also providing electrical power for external or peripheral devices. For example, the load management system may provide electrical power to multiple notebooks or notebook batteries through multiple

switched power ports, while also providing electrical power for an accessory such as a printer, projector, scanner, or other device, through an un-switched power port. Accordingly, the load management system **200** can be helpful for charging notebook batteries, while still allowing use of the peripheral devices and accessories that are all powered using a single power source insufficient to fully power all connected devices simultaneously.

In some cases the load management system may be incorporated within a battery charging station, such as a desktop charging station (e.g., as in FIGS. 5A-5D) or a notebook charging cart (e.g., as shown in FIGS. 6 and 7). Embodiments of the invention are not limited to notebook applications, however, and may be directed to providing power for a wide variety of electrical devices (i.e., electrical loads). For example, the electrical loads **204** can include devices such as a tablet computer, a cell phone, a smart phone, a personal digital assistant, a camera, a music player, and/or a global positioning satellite (GPS) device, among others.

FIG. 3 is a flow diagram illustrating a method **300** for applying power to a number of un-switched and switched electrical devices in accordance with an embodiment of the invention. According to one embodiment, the method **300** can be implemented with a controller configured to perform the steps in the method, such as the controller **208** described with respect to the load management system **200** in FIG. 2. According to one aspect, the illustrated method **300** generally enables a power distribution scheme in which a limited amount of available input power is distributed among a number of intermittent, switched loads, and if applicable, one or more continuous, un-switched loads. In some cases the method **300** also allows for prioritizing distribution of the input power. For example, in some cases priority is given to certain un-switched loads to provide full operation on-demand. In some cases power remaining after providing for the un-switched loads is applied to lower priority loads and may be switched between a between groups of lower priority loads to maximize the capability of the remaining input power.

Returning to FIG. 3, in this example the method **300** generally includes measuring and/or determining the current drawn by certain loads, grouping a number of switched loads based on the current measurements/determinations, and then applying power to the groups of switched loads one at a time. While a number of steps are illustrated in an order in FIG. 3, it should be appreciated that the steps in the method need not necessarily be performed in the illustrated order. In addition, while the method **300** is discussed in terms of applying power to "devices", it should be understood that the method is considered applicable to electrical loads in general.

In cases in which power is to be applied to un-switched or continuously powered loads, a first step in the illustrated method **300** can include providing power to any un-switched devices and measuring the current drawn by those devices (**302**). Referring to FIG. 2, this step could include, for example, applying electrical power to the auxiliary power output **212** and then measuring the current drawn by the auxiliary output **212** using the current sensor **216** coupled to the controller **208**. In addition, this step could include deactivating the switches **206** and applying electrical power to the networking power output **214** and then measuring the current drawn by the output **214** with the first current sensor **210** coupled to the controller **208**. After measuring or otherwise determining the currents (**302**), the current values may be stored in memory for future use.

Returning to FIG. 3, the method **300** further includes determining a switched current limit (**304**) for use in grouping electrical loads/devices. As referenced above, a switched cur-

rent limit is a determined threshold that represents a limit for the amount of electrical power that is available for switched loads at any one time. The switched current limit can be determined using a number of factors, including, for example, the current capacity or a current limit of the electrical power input as well as currents drawn by un-switched loads and measured in step 302. According to one embodiment, the switched current limit is calculated by determining the current capacity/limit of the electrical power input and then subtracting any measured or otherwise known currents associated with un-switched loads.

In some cases determining the switched current limit (304) also includes adjusting the switched current limit to account for variations in line voltage received at the electrical power input. For example, during operation, changes in line voltage affect the available source current. To account for this type of variation, the switched current limit can be adjusted down (e.g., by 10-20%) to allow for increasing input currents due to input voltage drops caused by other loads on the source distribution lines. Providing this type of hysteresis can in some cases help prevent or reduce the likelihood of false alarms due to constant power switching among loads and re-checks of the currents when the load is near the maximum of the switched current limit. In some cases the switched current limit may also be set to account for variations in line voltage in different areas of the world, such as the U.S. or Europe. For example, some embodiments of the invention compensate for world voltage source ranges by automatically limiting the maximum current regardless of the line voltage.

Returning to FIG. 3, the method 300 also includes measuring the current drawn by each switched electrical load or device (306). For example, referring to FIG. 2, the controller 208 is configured to measure the current associated with each of the switched power outputs 204 using the current sensor 210. After measuring the current drawn by each output, the measured currents can be saved in memory for future use.

With continued reference to FIG. 2, in some cases the current drawn by each output 204 is determined by switching on each output 204 one at a time, measuring the current drawn by the load coupled to the output, saving the measured current value, switching power off to that particular output, switching power to the next output, and starting the sequence over. This sequence allows for measuring the currents associated with the switched outputs 204 one at a time with the single current sensor 210. This method can also reduce the likelihood that too much power will be requested from the power input 202 during initialization of the power scheme, thus decreasing the risk of an early overcurrent fault.

In some cases a built-in delay is provided between switching power to each power output 204 and measuring the current drawn by the output. For example, the controller 208 may be configured to activate one of the switches 206 to apply power to a power output 204 and an associated load, and then wait for some time (e.g., several milliseconds) before measuring the current associated with that power output 204 and load. This procedure can help account for variations in how different electrical loads power up (e.g., to account for ramping currents, etc.) and ensure that accurate current measurements are made for each power output 204.

Returning to FIG. 3, after the currents of each switched device are measured (306), the currents associated with any un-switched loads are measured (302) and the switched current limit is determined (304), the method 300 further includes grouping (308) the switched outputs and associated electrical loads into one or more load groups based on the switched current limit and the measured currents. The load groups are thus defined to include one or more of the switched

outputs and corresponding switched electrical loads. Taking into account the determined switched current limit associated with the electrical power input, each group preferably includes a number of switched outputs and loads, but the sum of the measured currents associated with the selected outputs/loads does not exceed the switched current limit. Accordingly, upon switching power to a particular load group, the combined current draw of the outputs/loads within the load group will not be greater than the previously determined switched current limit.

A number of methodologies can be used to group the switched outputs and switched loads together and embodiments of the invention are not intended to be limited to only certain methods. According to some embodiments, the step 308 seeks to maximize the number of switched outputs and devices within a single load group so that as many possible switched outputs/loads will be powered at a time without exceeding the previously determined switched current limit. In certain embodiments different combinations of switched outputs/loads may be evaluated by adding the saved current measurements for a particular group of switched outputs/loads and comparing the result to the switched current limit. If the combined current draw is greater than the switched current limit, a smaller group or subset of the switched outputs/loads may then be evaluated. This approach may proceed until the largest combination of switched outputs/loads with a combined current draw below the switched current limit is determined. After determining the makeup of a first load group in this manner, the remaining switched outputs/loads can then be grouped into additional load groups in the same manner.

Following the grouping of the switched outputs and corresponding electrical loads, the method 300 includes applying power to each of the load groups (310). In some embodiments this involves activating switches to apply electrical power from the common power source to the load groups according to a power sequence. In certain cases the electrical power may be applied to each load group for a determined period of time before removing power from the load group and applying power to the next load group in the sequence. The sequence for applying power to the load groups can place the load groups in any desired order. In some embodiments the power sequence places the load groups in order from the load group with the greatest current draw not exceeding the switched current limit first to the load group with the lowest current draw last.

According to some embodiments, as power is removed from one load group and applied to the next load group in the power sequence, short delay is inserted between removal and subsequent application to limit inrush currents from multiple electrical loads being connected to the electrical power input at the same time. For example, in some cases the controller 208 of the system 200 shown in FIG. 2 may be configured to deactivate one group of switches 206, then delay approximately 100 ms, and then activate another group of switches 206 to apply power to another load group.

After applying power to one of the load groups in step 310, the method 300 determines whether all load groups have received power at step 314. If not, the method advances to the next load group in the power sequence (316) and switches power to the next load group. After all load groups have been powered according to the power sequence, the method 300 returns to the beginning of the process to re-measure the currents of the switched outputs and switched loads (306), re-measure the currents of each un-switched device (assuming the presence of one or more un-switched devices) and re-determine the switched current limit (304) to the extent

necessary. Based on this updated information, the method re-groups (308) the switched outputs/loads. During re-grouping, the same procedure of maximizing the number of switched outputs/loads in each load group can be followed in certain instances. Using the same procedure during the second and subsequent iterations of this process can be especially useful for charging batteries. For example, as previous cycles increase the charge of the batteries, an increasing number of batteries (i.e., switched loads) can be included in the same load group. Depending upon the extent of the re-grouping, the power sequence may be revised to activate switches for applying power to the desired switched outputs/loads. The process of re-measuring currents and regrouping switched outputs/loads continues as needed until power is no longer needed or a change in the process is necessary.

One type of event that can interrupt the method 300 described above is a change to the switched electrical loads and/or un-switched electrical loads that causes an increased current draw from the electrical power input above the switched current limit. According to some embodiments, the method 300 also includes monitoring (312) the switched and un-switched loads to determine if a current increase occurs. Although the monitoring step 312 is illustrated at a particular point in method 300, it is contemplated that in some embodiments the monitoring step 312 may be ongoing throughout the method 300, simultaneous with the other steps. Upon detecting (314) an increase in the current rising above the switched current limit, the method 300 may interrupt the current activities to once again start the process at the beginning so that the currents can be re-measured and the switched electrical loads can be re-grouped as necessary to prevent an immediate overcurrent event. In addition, the switched current limit can be adjusted as necessary based on the detected increase in current. For example, if a user abruptly turns on a device connected to an un-switched power output causing an increase in un-switched current flow, the switched current limit can be adjusted to reflect the decrease in available current for the switched loads, thus giving priority to the un-switched load.

FIG. 4 is an illustration of an indicator panel 400 for a load management system in accordance with an embodiment of the invention. In some cases the indicator panel provides an indication to a user of the current state of the load management system, including scanning, powering, fault, etc. In some cases the load management system has the following modes:

- Scanning
- Powering
- Fault
- Not powered up
- Powered up
- Sensing something attached to the auxiliary power receptacle
- Not sensing something attached to the auxiliary power receptacle.

The following description is just one possible example of an indication scheme. When the load management system measures currents for the attached loads/devices, the loads (1, 2, 3, 4 . . .) that are being scanned are indicated by illuminating the number 402 that represents the load and flashing the number at a fast rate (e.g., 1/4 second on, 1/4 second off). In some cases the loads are individually scanned so there will never be more than one load number flashing at one time during the scan. Once scanning all switched loads is complete and the load groups that can be powered at one time are determined, those load groups will be powered on and indicated to the user by illuminating all of the applicable load

numbers (1, 2, 3, 4 . . .) with a slow flashing light (e.g., 1 second on, 1 second off). As discussed above, a load group can include any combination of switched loads, and thus any combination of load indicators 402 may flash.

In some circumstances, when there is a fault condition (e.g., overcurrent, high temperature, etc.), none of the load indicators 402 will be illuminated. If the fault condition is a high temperature, the high-temperature icon 404 will be illuminated and flashing (e.g., 1/2 second on, 1/2 second off). When the load management system is coupled with an input power source, a power-on icon 406 can be illuminated. When the system senses an attached load on its un-switched power output (e.g., an auxiliary power receptacle), the power plug icon 408 can illuminate. When there is nothing attached to the un-switched power output, or a load is attached and the power is sufficiently low (e.g., 0.2 amps) or the load power is off, the power plug icon 408 will not be illuminated.

Embodiments of the invention, including aspects related to the load management system 200 and method 300 for applying power described above can be implemented in a wide variety of application-specific embodiments. Embodiments of the invention are not limited to any particular application, but may be directed to providing and managing power for a wide variety of electrical loads, including, for example, electrical devices such as notebook and tablet computers, cell phones, smart phones, PDAs, cameras, music players, and/or GPS devices, among others. As one example, a load management system such as one described herein could be provided within or in conjunction with a vehicle power system in order to power and/or charge a number of devices (e.g., GPS, cell phones, video players, music players, etc.) within the vehicle.

As mentioned above, in some cases an embodiment of the invention may be incorporated within a battery charging station, such as a desktop charging station or a notebook charging cart. These particular applications will now be discussed in more detail.

FIGS. 5A-5D are perspective views of a notebook battery charging station 500 in accordance with an embodiment of the invention. As is known, most notebook/laptop computers have one or more removable batteries that can be disconnected and uncoupled from the laptop for charging, maintenance, replacement, etc. In some embodiments of the invention, the charging station 500 includes a housing 502 configured to receive and/or hold one or more laptop batteries 504. The charging station 500 also includes one or more corresponding charging circuits 506 and cables 508 and/or connectors 510 for coupling the one or more batteries 504 to the charging circuits 506. The charging station 500 can be configured to hold as many laptop batteries as desired. In some embodiments, the station holds at least 5 laptop batteries. In other embodiments, the station is configured to hold more than 10 batteries, (e.g., up to 20, 30, or 40 batteries).

Turning to FIG. 5D, the charging station 500 includes circuitry adapted to charge the one or more batteries coupled to the station. A power supply system can be provided for charging the plurality of batteries when received in the station. The power supply system is useful for recharging the batteries of the laptops. The power supply system includes a device to receive power into the cart, such as a male power cord extending from the cart or a female receptacle in or on the charging station. Embodiments of the power supply system include a power brick 520 that in some cases converts AC power to DC power which is ultimately routed to each laptop battery stored within the station 500. In some embodiments an external AC/DC power converter provides DC power that is received at the charging station. In some cases the charging

circuitry includes one or more indicators, such as LEDS **518**, that illuminate when the charging circuitry is currently in use.

In some embodiments the charging station **500** may be configured to receive entire laptops, rather than only a laptop battery. In such cases, a networking connection (e.g., Ethernet) can be provided for connecting the laptop computers to a network when stored in the charging station. Such a connection is useful for providing software updates to the laptops when they are not in use. Of course, the charging station **500** can provide each laptop with other connections. Further, one or more power outlets (not shown) can be provided on the exterior of the charging station **500** if desired. Such power outlets allow for accessories such as printers and projectors to be plugged into the charging station so that additional power cords do not have to be run from the station to the wall.

In some cases simultaneously charging many notebooks or notebook batteries can exceed the limited current capabilities of typical wall outlets found in homes, schools, and business, as set forth by the National Electrical Code and foreign equivalents. In addition, the power requirements of the multiple notebooks/batteries **504** can exceed the capacity of the DC power source **520** that provides the bulk charge current for the battery charging electronics. According to some embodiments, the charging station **500** incorporates a load management system, such as the system **200** illustrated in and described with respect to FIG. **2**. The load management system interfaces between the DC power source **520** and the charging circuits **506** to manage the electrical power received from the power source **520** and distribute it to the charging circuits and thereafter the batteries **504** in the manner described above without exceeding the branch-circuit current capability as set forth in the National Electrical Code or the capability of the local DC power source. Referring briefly to FIG. **2**, for example, the power source **520** of the charging station can interface with the load management system **200** at the electrical power input **202**, although a hardwired or other connection may be used. In a similar fashion, each of the charging circuits **506** can interface with each of the electrical power outputs **204** though, e.g., a hardwired or other connection. In addition, the un-switched auxiliary power output **212** can be coupled to an exterior power outlet to the extent one is included with the charging station **500**.

FIGS. **6A-6D** are views of a laptop charging/storage cart **600** in accordance with an embodiment of the invention. FIGS. **7A-7B** are perspective views of another laptop cart **700** in accordance with another embodiment of the invention. The carts can include any structure useful for holding a plurality of laptop computers or other mobile computing devices and providing power and/or network connectivity to the laptop computers. Multiple examples of carts that can be useful for storing and/or charging laptop computers and other mobile computing devices are disclosed in co-owned and copending U.S. patent application Ser. No. 13/025,782, the entire content of which are hereby incorporated herein by reference.

Returning to FIGS. **6A-7B**, as shown, the carts **600**, **700** can each include a cabinet **630** defining an interior space for storing a plurality of laptop computers. The interior space may in some cases include a laptop docking station **650** for each laptop disposed in the cart. As shown in FIGS. **6A-7B**, in some embodiments the cabinets **630** include a door assembly **670** having one or more doors to close the interior space bounded by a top, bottom, and four sides. Such doors can be of any style including, sliding, openable from the top, or swingable outwardly. In some embodiments, the door may optionally be locked to secure the mobile computing devices within the cart. In some embodiments, wheels **610** can be positioned on an underside of the cabinet **630** to facilitate easy

movement of the carts. Further, handles **620** can be provided to facilitate the movement of the cart.

As shown in FIGS. **6B-6C**, a plurality of docking stations **650** can be configured to hold the laptop computers in a generally vertical position, or as shown in FIG. **7A**, the plurality of docking stations **650** can be configured to hold the laptop computers in a generally horizontal orientation positioned on a shelf **654**. The carts can be configured to hold as many laptops as desired. In some embodiments, the carts hold at least 10 laptop computers in their interior spaces. In other embodiments, the carts are configured to hold between 10 and 40 (e.g., 20 and 30) laptops in their interior spaces.

Further, as shown in FIGS. **7B-7D**, one or more auxiliary power outlets **730** can be provided on the exterior of any cart. Such power outlets allow for accessories such as printers and projectors to be plugged into the cart so that additional power cords do not have to be run from the cart to the wall. FIGS. **7C-7D** are front perspective views of auxiliary power outlets **730** having a cover **790** (in the open position) to reduce the likelihood that foreign objects will be placed in the auxiliary power outlet **730**. In FIG. **7C**, the cover is open to provide access to a United States style power outlet, while in FIG. **7D** the cover is open to provide access to a European style power outlet.

An network connection (e.g., Ethernet) system (not shown) can be provided for connecting the plurality of laptop computers to a network when stored within the interior space. The network connection system includes at least one device for a cart to communicate with the network. In some embodiments, this device includes a wire extending from the cart. In other embodiments, the cart includes a wireless transmitter that allows the cart to communicate with the network. Ultimately, the cart allows for communication between each laptop stored in the cart and the network. Such a connection is useful for providing software updates to the laptops when they are not in use. In general, these systems are internal to a cart and are not easily accessible to users. Of course, the carts **600**, **700** can provide each laptop with other connections.

In some embodiments, a cart includes an air circulation system to cool the plurality of laptop computers when they are in the interior space. The air circulation system can include at least one fan **770** disposed in an outer surface of the cabinet **630** to facilitate air exchange between the interior and the exterior of the cabinet. In some embodiments, one or more passive vents are provided in the exterior of the cabinet to facilitate air circulation.

A power supply system can be provided for charging the plurality of laptop computers when stored within the interior spaces of the carts **600**, **700**. Each power supply system includes a device to receive power into the cart, such as a male power cord extending from the cart or a female receptacle in or on the cart. Embodiments of the power supply system convert AC power to DC power and ultimately route the power to each laptop stored within the carts **600**, **700**. The power supply system may also route power to other subsystems within the carts **600**, **700**, including the auxiliary outlets, networking circuitry, and/or air circulation system described above.

As noted above with respect to the charging station **500** illustrated in FIGS. **5A-5D**, in some cases simultaneously charging many notebooks or notebook batteries can exceed the limited current capabilities of typical wall outlets found in homes, schools, and business, as set forth by the National Electrical Code and foreign equivalents. In addition, the power requirements of the multiple notebooks/batteries **504** can exceed the capacity of the DC power source **520** that provides the bulk charge current for the battery charging

15

electronics. These same limitations can also affect the performance of laptop charging/storage carts, such as the carts **600**, **700** described herein.

According to some embodiments, the power supply system of a laptop cart incorporates a load management system, such as the system **200** illustrated in and described with respect to FIG. **2**. In certain embodiments, the load management system interfaces between the AC input box of the power supply system and the various subsystems within the cart powered by the power supply system. The load management system manages the electrical power received from the AC input and distributes it to the docking stations **650** within each cart **600**, **700**, as well as to the auxiliary outlets, networking circuitry, and/or air circulation system described above. As described above (e.g., with respect to FIGS. **2-3**), the load management system is configured to distribute electrical power to these systems within the carts **600**, **700** without exceeding the branch-circuit current capability as set forth in the National Electrical Code.

FIG. **8** is a high-level schematic of a power supply system **800** for a notebook charging cart in accordance with an embodiment of the invention. As just one example, the power supply system **800** can be incorporated within either of the carts **600**, **700** discussed above. The power supply system **800** includes an AC input box **850** that is configured to receive power into the cart, and may include a female receptacle in or on the cart or a male power cord extending from the cart. The AC input box **850** is coupled to a load management system **801**, also referred to in this example as a power control box. The load management system **801** manages the power received from the AC input box and distributes it to a number of subsystems within the power supply system. According to an embodiment of the invention, the load management system **801** provides functionality similar to the system **200** described with respect to FIG. **2**.

For example, the load management system **801** includes an electrical power input receptacle **802** that couples with the AC input box and receives electrical power from the AC input box. The system **801** also includes a number of switched power output receptacles **804**, which are coupled to a number of power extension strips **852**. Each extension strip **852** includes multiple female power receptacles for plugging in up to five laptop computers (in this embodiment a sixth receptacle is not used), thus providing power for up to thirty laptop computers within the cart. The load management system **801** also includes a networking power output **814** which is coupled to a networking power box **854**, and an auxiliary output **812** which is coupled to an auxiliary outlet **856**. The load management system **801** receives operating power from an AC/DC converter **858** through a power input **822**. In addition, in this embodiment the load management system **801** also includes three power outputs **860** coupled to a number of fans **862** which make up part of an air circulation system of the cart. Further, the load management system **801** includes a power output **864** for powering a temperature sense board **866**, and power outputs **868** for powering an LED indication board **870**.

As discussed above with respect to FIG. **2**, the load management system **801** in FIG. **8** includes a controller that is configured to distribute the available electrical power from the power input **802** to the switched power outputs **804** by grouping the power outputs **804** and then selectively applying the electrical power to the groups of power outputs (and by extension, the power extension strips **852** and laptops coupled thereto) according to a power sequence. As with the system **200**, the load management system **801** also provides unswitched (e.g., continuous) electrical power to one or more

16

power outputs, including in this case the auxiliary power output **812** and the networking power output **814**, as well as the power outputs **860**, **864**, and **868** for the air circulation system fans **862**, the temperature sense board **866**, and the LED indication board **870**, respectively. Of course any number of additional power outputs can be included in the load management system **801**, and any combination of the outputs can be switched or un-switched depending upon, for example, the importance of the functions provided and the desirability of providing those functions uninterrupted, e.g., un-switched.

As discussed with respect to the system **200**, the system **801** also includes a number of current sensors (not shown) coupled to the switched power outputs **804** and the un-switched power outputs to help determine the currents drawn by the various subsystems coupled to the load management system **801**. The controller (not shown) can then use those currents, along with a current limit of the power source to group the switched outputs and apply power to each of the switched outputs according to a determined power sequence as discussed above with respect to the system **200**. Accordingly, the load management system **801** allows the power supply system **800** to prioritize electrical power distribution for un-switched loads, while providing the remaining available power to the laptop computers through the switched power outputs **204** in an efficient, sequenced charging scheme.

According to certain embodiments of the invention, a load management system is configured to monitor the currents of the notebook computers or individual batteries and group them in an efficient way to charge the most notebooks/batteries at the same time without exceeding the branch circuit current limits or bulk power source limits. After a specified period of time, the system switches power from a first grouping of notebooks or batteries to a second grouping of notebooks/batteries and provides power to the second group for a specified period of time. As many groups as desired can be provided, depending on the number of notebooks the cart is adapted to hold. This monitoring of current and grouping continues until all notebooks or batteries are removed from the cart/charging station or the charging is completed. If additional notebooks or batteries are added to the cart/charging station, the currents may be measured again and notebooks and batteries can be re-grouped if necessary for optimal charging. According to some embodiments, a system that couples to full laptop computers, may automatically switch the Ethernet connections on by applying power to them after the charging is completed the system so the notebooks can be managed after they have sufficient charge.

According to certain embodiments, a load management system also monitors to see if an external device is plugged into any provided auxiliary power receptacles. If the system detects such an external device it can give the device top priority and automatically remove or reduce power to the notebooks, batteries, networking circuitry, and other lower priority subsystems. If the system detects the external device has been removed, it can begin applying power to the other subsystems. Accordingly, in some embodiments a system automatically and selectively directs power to an external device, notebook/battery charging systems, and notebook management systems, in that order of priority. Further, in some embodiments, the system monitors the temperature of the cart or charging station and if it detects an over-temperature situation, it removes power to all notebooks and/or batteries. In some embodiments, the controller automatically re-applies power when the over temperature situation has been corrected. In some embodiments there is at least a 30 mS

delay before an over temperature detection to prevent a false indication during electromagnetic interference events. An indication to the user of an over temperature situation can be provided by a blinking LED on an LED indication board.

FIGS. 9A-9C are a flow diagram 900 illustrating steps and decision points for charging multiple notebook computers in accordance with an embodiment of the invention. The flow diagram 900 generally illustrates a methodology for charging thirty notebook computers in a setting with a 100/110/120 Volt, 15 Ampere ("Amp") input power source, and corresponds to the embodiment of the power supply system 800 described with respect to FIG. 8. The charging methodology begins with an initialization setup 902. The initialization setup 902 begins upon an initial powering on of the power supply system and load management system. First steps in the initialization setup 902 include turning on a Power On LED, a logo LED, and the auxiliary power output.

The initialization sequence then completes an initial test of the load management system 801 to determine if any over-currents exist prior to initiating the charging sequence. During the test, each switched power output 804 is turned on for one second, along with a corresponding coupled power extension strip 852 and any coupled notebook computers. FIGS. 9A-9C refer to a switched power output and extension strip as a "bank". A charge timer is then set to ten minutes and the current of each bank (i.e., switched power output 804 and extension strip 852) is scanned for thirty seconds each. Following is a five-second current scan of the networking power output 814. Following the scans, the measured currents are saved to memory.

The charging methodology of FIGS. 9A-9C includes a first query 904 of the currents measured during the initial scan in the setup 902 to determine if an initial overcurrent is present. The first query 904 checks if the currents measured during the one second scan or the thirty second scan in addition to current detected on the auxiliary power output ("AUX") and the networking power output ("SW") are greater than twelve Amps. The query uses twelve Amps as the comparison point because the National Electrical Code (NEC) sets the limits for 15-amp site branch wiring to 12-amps. (The foreign equivalent for 10-amp branch circuits is 8-amps.) Accordingly, devices plugging into wall receptacles cannot exceed 12 Amps in North America. If the measured currents are greater than 12 Amps, the load management system enters an endless loop 906 in which the LEDs are flashed at a rapid rate to indicate the overcurrent event.

If the measured currents are less than or equal to 12 Amps, a second query 908 is made to determine if the system's temperature is within a desired range. If not, the system turns off the switched power outputs (i.e., Banks 1-6) and flashes the High Temp LED. If the system is within temperature range, then the auxiliary current is compared to 0.2 Amps in query 910 to make a determination as to whether or not an external device coupled to the auxiliary power output is turned on and the system illuminates the AUX LED at 912.

Following these initial evaluations, the charging methodology begins comparing the currents measured on each switched power output in order to group the power outputs into one or more load groups and then apply power to the load groups. The methodology follows an iterative approach in which different combinations of switched power outputs are compared to a switched current limit to determine the groupings. In this case, the switched current limit is equal to ten Amperes less the currents on the auxiliary and networking outputs (10A-AUX-SW). Ten Amperes is used instead of the

actual NEC limit of twelve amperes in order to add in hysteresis around the threshold to avoid constant switching when levels near the threshold.

The comparisons begin with query 920, in which it is determined whether a combination of all six switched power outputs (all six "banks") has a combined current less than the switched current limit. If they do, only one load group is formed including all the banks and this is powered on for a ten minute period at 922. After the ten minute period expires, the process starts over again. If at any time during the current comparisons the total current is greater than twelve amps (query 924), the process is immediately interrupted to re-measure the various currents (step 926) and start the grouping process over.

If the current on all six banks is not less than the switched current limit at query 920, then the comparison continues at query 930 in which it is determined if the first five banks have a combined current less than the switched current limit. If so, a first load group including the first five banks is powered for ten minutes at 932, and then a second load group including only bank six is powered for ten minutes.

As can be seen in FIGS. 9A-9C, according to this embodiment, a large number of load groupings (defined in rectangular boxes 940) are possible according to the illustrated charging methodology depending upon the currents measured on each individual switched power output, as well as the currents measured on the AUX and SW outputs. In addition, in this embodiment the query 924 is continuously made throughout the various current comparisons and if at any time the combined total current is greater than twelve Amps, then the sequence is interrupted and the currents are re-measured in order to re-group the power outputs into load groups whose current does not exceed the switched current limit.

FIGS. 10A-10B, 11A-11C, and 12A-12B illustrate additional charging methodologies similar in many respects to the methodology illustrated in FIGS. 9A-9C. The methodology of FIGS. 10A-10B corresponds to a computer cart with twenty laptop computers being powered with a 100/110/120 Volt, 15 Amp input power source. FIGS. 11A-11C, and 12A-12B correspond to computer carts powered by a 220/230/240 Volt input source. FIGS. 11A-11C illustrate a thirty-notebook methodology, while FIGS. 12A-12B illustrate a twenty-notebook methodology.

Thus, embodiments of the invention are disclosed. Although the present invention has been described in considerable detail with reference to certain disclosed embodiments, the disclosed embodiments are presented for purposes of illustration and not limitation and other embodiments of the invention are possible. One skilled in the art will appreciate that various changes, adaptations, and modifications may be made without departing from the spirit of the invention and the scope of the appended claims.

What is claimed is:

1. An electrical load management system for charging batteries, comprising:
 - an electrical power input configured to couple the load management system with a common power source;
 - a plurality of electrical power outputs configured to couple the load management system with a plurality of electrical loads, each electrical load comprising a battery to be charged;
 - a plurality of switches coupled between the power input and the power outputs;
 - a first current sensor coupled to the power outputs for sensing a current drawn by one or more of the power outputs; and

19

a controller coupled to the plurality of switches and the first current sensor, the controller configured to:

carry out an iterative grouping process in which the controller is configured to

measure with the first current sensor a current drawn by each of the plurality of electrical loads respectively coupled to the plurality of electrical power outputs, each electrical load comprising a battery to be charged,

group the plurality of power outputs and respective electrical loads into a plurality of load groups such that a sum of the measured currents of the electrical loads in each load group does not exceed a switched current limit that defines a limit for current drawn by the electrical power outputs, the grouping comprising forming a first load group with a first number of the power outputs and respective electrical loads, then forming a second load group with a second number of power outputs and respective electrical loads not in the first load group, and

then continuing to form additional load groups as long as any of the power outputs and respective electrical loads remain ungrouped, each successive additional load group having a number of the currently ungrouped power outputs and respective electrical loads,

operate the plurality of switches to apply electrical power from the common power source to each of the load groups to charge the batteries forming at least part of the electrical loads within each of the load groups, and to apply the electrical power to only one load group at a time while removing the electrical power from the other load groups, and

restart the iterative grouping process after applying electrical power to each of the load groups; and

continue the iterative grouping process at least until all of the plurality of power outputs and respective electrical loads are combined in one load group.

2. The system of claim 1, further comprising an indicator coupled to the controller, wherein the controller is configured to activate the indicator based on a state of the system.

3. The system of claim 1, further comprising a temperature sensor coupled to the controller, wherein the controller is further configured to receive a temperature signal from the temperature sensor and activate one or more of the plurality of switches to turn off one or more of the power outputs based on the temperature signal.

4. The system of claim 1, wherein the electrical power input is configured to couple the load management system with an alternating current (AC) power source, the plurality of switches are configured to switch AC power, and the plurality of electrical power outputs are configured to couple the load management system with a plurality of electrical loads requiring AC power.

5. The system of claim 1, wherein the electrical power input is configured to couple the load management system with a direct current (DC) power source, the plurality of switches are configured to switch DC power, and the plurality of electrical power outputs are configured to couple the load management system with a plurality of electrical loads requiring DC power.

6. The system of claim 1, further comprising an un-switched power output coupled to the electrical power input and a second current sensor coupled to the controller, the un-switched power output configured to couple the load management system with a corresponding un-switched elec-

20

trical load and the second current sensor configured to sense a current drawn by the un-switched power output.

7. The system of claim 6, wherein the controller is configured to measure with the second current sensor a current drawn by the un-switched electrical load and determine the switched current limit based on the measured current drawn by the un-switched electrical load.

8. The system of claim 7, wherein the controller is configured to measure the current drawn by the un-switched electrical load and determine the switched current limit before starting the iterative grouping process.

9. The system of claim 8, wherein the controller is further configured to

determine the current drawn by the un-switched electrical load during the iterative grouping process; and

if the determination of the current indicated an increase in the current drawn by the un-switched load, then

interrupt the iterative grouping process,

re-determine the switched current limit based on the increase in the current drawn by the un-switched load, and

restart the iterative grouping process using the re-determined switched current limit.

10. The system of claim 1, wherein the controller is further configured to measure the current drawn by each of the plurality of electrical loads throughout the iterative grouping process, and if the measured currents indicated that an increase in the current drawn by the electrical loads within a load group is above the switched current limit, then interrupt and restart the iterative grouping process.

11. A battery charging station, comprising:

an electrical power input configured to couple the charging station with a common power source;

a plurality of switched electrical power outputs configured to couple the charging station with a plurality of electrical loads comprising batteries to be charged;

a plurality of switches coupled between the power input and the switched power outputs;

a first current sensor coupled to the switched power outputs for sensing a current drawn by one or more of the switched power outputs;

an un-switched output coupled to the electrical power input and configured to couple the charging station with an un-switched electrical load;

a second current sensor coupled to the un-switched power output for sensing a current drawn by the un-switched power output; and

a controller coupled to the plurality of switches, the first current sensor, and the second current sensor, the controller configured to:

carry out an iterative grouping process in which the controller is configured to

measure with the first current sensor a current drawn by each of the electrical loads respectively coupled to the switched power outputs, each electrical load comprising a battery to be charged,

group the plurality of switched power outputs and respective electrical loads into a plurality of load groups such that a sum of the measured currents of the electrical loads in each load group does not exceed a switched current limit that defines a limit for current drawn by the electrical power outputs, comprising

forming a first load group with a first number of the switched power outputs and respective electrical loads,

21

then forming a second load group with a second number of the switched power outputs and respective electrical loads are not in the first load group, and

then continuing to form additional load groups as long as any of the switched power outputs and respective electrical loads remain ungrouped, each successive additional load group having a number of the currently ungrouped power outputs and respective electrical loads,

operate the plurality of switches to apply electrical power from the common power source to each of the load groups to charge the batteries forming at least part of the electrical loads within each of the load groups, and to apply the electrical power to only one load group at a time while removing the electrical power from the other load groups, and restart the iterative grouping process after applying electrical power to each of the load groups; and continue the iterative grouping process at least until all of the plurality of switched power outputs and respective electrical loads are combined in one load group.

12. The charging station of claim **11**, wherein the controller is configured to measure with the second current sensor the current drawn by the un-switched power output and determine the switched current limit before starting the iterative grouping process.

13. The charging station of claim **12**, wherein the controller is further configured to

22

determine the current drawn by the un-switched power output during the iterative grouping process; and

if the determination of the current indicates an increase in the current drawn by the un-switched power output, then interrupt the iterative grouping process,

re-determine the switched current limit based on the increase in the current drawn by the un-switched load, and

restart the iterative grouping process using the re-determined switched current limit.

14. The charging station of claim **11**, wherein the controller is further configured to measure the current drawn by each of the switched power outputs throughout the iterative grouping process, and if the measured currents indicate that an increase in the current drawn by the switched power outputs within a load group is above the switched current limit, then interrupt and restart the iterative grouping process.

15. The charging station of claim **11**, wherein the plurality of electrical loads to be charged comprise at least one of a notebook computer, a tablet computer, a cell phone, a smart phone, a personal digital assistant, a camera, a music player, and a global positioning satellite device.

16. The charging station of claim **11**, wherein the charging station comprises a notebook charging cart.

17. The charging station of claim **11**, wherein the charging station comprises a stationary battery charging station.
